It is not well understood how the sternocleidomastoid (SCM) muscle is affected in patients who have sustained a neck injury. This study evaluates the changes in the SCM muscle as a result of repetitive and sustained cervical movements. Surface electromyographic (EMG) activity from the SCM muscle was recorded in four patients and nine healthy control subjects. Subjects in each group underwent five to eight 10-minute repetitive cycles of neck flexion-extension and lateral flexion-extension movements, with the head restrained. EMG signals were processed using a time-frequency algorithm and compared between the patient and control groups. EMG activity was lower in the patient group than the control group at low-medium frequencies (10-80 Hz) during the repetitive flexion-extension and lateral flexion-extension movements. This difference was not found during the sustained lateral flexion-extension movement. Differences were detected at the highest frequencies (80-150 Hz). EMG activity was higher in the patient group than the control group in the lateral flexion-extension and sustained lateral flexion-extension movements. This difference was not found in the repetitive flexion-extension movements. These results may indicate an altered pattern of nerve conduction and increased muscle tension. The potential therapeutic benefit of such information is discussed.Diethylstilbestrol, also referred to 2d92ce491b
